ABSTRACT

The nonlinear evolution of the internal kink mode is studied in toroidal geometry for noncircular cross section tokamak plasmas. The study is focused on very low shear and hollow q profiles with $q(\rho) \geq 1$ for which the internal kink is unstable, in the latter case even at $\beta = 0$. The nonlinear evolution is dominated by ideal magnetohydrodynamics (MHD), and the instability saturates, giving a quasi-helical shift to the magnetic axis. The nonlinear saturation is caused by increased field line bending. Time scales of $10^3 \tau_{Hp}$ and axis shifts of 20% are reached when changes in q on the order of 3×10^{-3} from the marginal profile are produced.

1. INTRODUCTION

Understanding the sawtooth oscillation in tokamaks is extremely important because this instability limits confinement at the plasma core. This instability is generally associated with the $m = 1$ mode and the presence of the $q = 1$ surface in the plasma. Despite much experimental, theoretical, and computational effort, the general behavior of the $m = 1$ instability resists complete understanding. Theoretically, this is largely because of its complicated nature in toroidal geometry. Depending on the type of q profile, the Lundquist number S , the value of plasma β , and the aspect ratio, the $m = 1$ instability changes character,¹ taking the form of resistive kink, tearing mode, or ideal kink. Each form corresponds to different linear properties and to a variety of nonlinear behavior, and each leads therefore to different predictions for experimental observations.

Experimentally, a wide variety of phenomena is associated with this instability. In large tokamaks that have low resistivity, the sawtooth crash occurs on a rapid time scale, suggesting an ideal MHD mechanism. For example, the observed sawtooth crash time for JET is about $100 \mu s$,² which is almost two orders of magnitude less than the prediction of Kadomtsev's resistive reconnection model.^{3,4} Analysis of a JET fast sawtooth collapse

reveals a rapidly growing $m = 1$ component in the soft X-ray emission and electron temperature profiles.²

To explain this rapid sawtooth collapse, Wesson proposed a model in which the ideal $m = 1$ instability is responsible for the crash.⁴ According to the model, to generate the sudden, precursorless disruption, such a mode must undergo a sharp transition from ideal stability to vigorous growth, so that slight diffusive changes in profiles can trigger a hard instability. The structure of this instability must also be global enough to induce the observed transition from peaked to hollow emissivity profiles, and it must occur at low plasma β consistent with experiment. Because of the rapidity of the crash and the high conductivity of large tokamaks, the collapse is postulated to involve no reconnection. Instead, the hot central plasma is shifted convectively as cooler plasma flows into the center, and together these form a configuration of 1/1 helicity. Reconnection then occurs on a longer resistive time scale after the collapse.

Two types of safety factor profile for which the internal kink is unstable at very low β and which lead to sharp linear stability boundaries are hollow (non-monotonic) profiles having an off axis $q_{\min} \approx 1$ and very low shear (flat) profiles with central $q_0 \approx 1$. Slightly hollow profiles have been obtained in transport simulations of sawtooth discharges,^{5,6} and very low shear profiles have been measured on ASDEX.⁷ By generalizing the linearized analysis of Bussac et al.,⁸ it has been shown¹ that both types of profile lead to an ideal instability having sharp stability boundaries at low β and eigenfunctions of dominant size in the plasma core.

Analytic calculations demonstrate that the ideal stability properties are strongly dependent on toroidal curvature, even to the extent that at low β opposite signs are obtained for δW in toroidal and cylindrical geometry. Even so, the nonlinear behavior of the $m = 1$ mode has been examined in cylindrical geometry for very low shear profiles^{9,10} and for hollow profiles,¹¹ with the plasma β chosen to provide growth rates commensurate with experimental values. Recently a nonlinear calculation in toroidal geometry has

been published¹² which shows many features in common with the rapid sawtooth. Clearly, systematic nonlinear calculations in toroidal geometry are necessary to gain a detailed understanding of the behavior of the $m = 1$ mode in tokamaks.

This paper first recounts the linear stability properties for hollow and low-shear q profiles with $q(\rho) \geq 1$. The internal kink stability boundary for these profiles is determined by the stabilization caused by field line bending, not by a change in the sign of δW_T . The effect of plasma cross section shaping is investigated, and the dominant shaping effects on stability come from modification of the field line bending, which changes the stability boundaries.

The main purpose of the paper is to study the nonlinear effects by calculating the time evolution of the instability. This evolution is dominated by ideal MHD dynamics, and the evolution time scale is close to γ^{-1} , where γ is the linear growth rate. The instability nonlinearly saturates at a finite size, causing a helical shift of the magnetic axis and a crescent-shaped distortion of the magnetic surfaces. The increased field line bending caused by this distortion is the cause of the saturation of the instability.

This paper is organized as follows: Sect. 2 discusses the features of the equations and equilibrium of particular interest here; linear stability is the subject of Sect. 3; in Sect. 4 the nonlinear stability results are presented; a discussion of the numerics is given in Sect. 5; and Sect. 6 contains a discussion of the physics results. Finally, conclusions concerning the likelihood that the studies presented here pertain to the rapid sawtooth crash are given in Sect. 7.

2. EQUILIBRIUM AND EQUATIONS

This paper examines the nonlinear behavior of the $m = 1$ internal kink instability for circular and noncircular plasmas in toroidal geometry, for both hollow and low-shear profiles in the framework of incompressible MHD. The instability studied in this work is more correctly identified as an $n = 1$ (n is the toroidal mode number) mode because of the

toroidal coupling of the poloidal components m . However, for the profiles studied here, the $m = 1$ poloidal component is dominant and the term $m = 1$ instability is generally used. The numerical calculations were done with an incompressible version of the initial value, ideal or resistive fixed boundary, MHD computer code, FAR.¹³ The numerical methods used in FAR are discussed in detail in Ref. 13, and solution of the incompressible equations is discussed in Ref. 14. Only a brief discussion of the model will be included here.

The FAR code solves the MHD equations in three spatial dimensions and in time starting from an initial equilibrium solution plus a small perturbation. The spatial part of the problem is represented in a straight-field-line magnetic flux coordinate system of the equilibrium. The coordinates are (ρ, θ, ζ) , where $0 \leq \rho \leq 1$ is a generalized minor radius flux surface label, $0 \leq \theta \leq 2\pi$ is a generalized poloidal angle, and $0 \leq \zeta \leq 2\pi$ is the toroidal angle. This coordinate system is used to define an average plasma minor radius a , which includes the effects of shaping

$$a^2 = \frac{R_0}{2\pi^2} \int R^{-2} d\tau, \quad (1)$$

where R_0 is the plasma major radius, R is the major radius coordinate, and the volume integral is taken over the entire plasma. Also defined is a shape-dependent inverse aspect ratio $\epsilon = a/R_0$. This inverse aspect ratio is, for shaped plasmas, distinct from the usual tokamak inverse aspect ratio $\epsilon_H = a_H/R_0$, where a_H is the horizontal minor radius. In this paper, we use this notation to distinguish the shape-dependent and usual aspect ratios. Three advantages associated with the use of flux coordinates are the ability to resolve radially localized singular layers, the ability to accurately represent the operator $\vec{B} \cdot \vec{\nabla}$, and the ability to treat shaped plasmas without reformulating the method of solution. The final advantage permits the study of shaping effects simply by varying the shape of the equilibrium cross section.

The equilibrium solution is calculated using the code RSTEQ,¹⁵ which solves the two-dimensional, axisymmetric Grad-Shafranov equation and maps the solution into the desired

flux coordinates. The equilibria used in this paper are determined for a safety factor profile $q(\rho)$ and a pressure profile $p(\psi_{\text{eq}})$, where ψ_{eq} is the equilibrium poloidal magnetic flux function. Throughout this work the pressure profile is chosen to be

$$p(\psi_{\text{eq}}) = p_0 \{ [\psi_{\text{eq}} - \psi_{\text{eq}}(a)] / [\psi_{\text{eq}}(0) - \psi_{\text{eq}}(a)] \}^2, \quad (2)$$

where p_0 is the pressure at the magnetic axis, $\psi_{\text{eq}}(0)$ is the value of ψ_{eq} at the magnetic axis, and $\psi_{\text{eq}}(a)$ is the value at the plasma edge.

The usual forms of the parameterizations for the equilibrium safety factor profiles used here are:

$$q(\rho) = q_{\text{min}} + \Delta q [1 - (\rho/\rho_{\text{min}})^2]^2 \quad (3)$$

and

$$q(\rho) = q_0 [1 + (\rho/\rho_0)^{2\lambda}]^{1/\lambda} - \Delta q_{\ell} e^{-\left(\frac{\rho^2 - \rho_{\text{min}}^2}{2\rho_{\text{min}}\Delta\rho}\right)^2}. \quad (4)$$

Equation (3) defines a hollow profile of depth Δq as measured from the magnetic axis to the minimum q_{min} at $\rho = \rho_{\text{min}}$. Certain generalizations of this profile will be defined later as they are needed. Equation (4) defines a locally hollow profile with a minimum of depth Δq_{ℓ} at ρ_{min} . Near ρ_{min} this hollow contribution is approximately Gaussian with a width of $\Delta\rho$. In most calculations presented here using Eq. (4), Δq_{ℓ} is chosen to be zero. Then, for appropriate choices of ρ_0 and λ , a low-shear profile results. In this paper the usual parameter choices are $\Delta q = 0.1$, $\rho_{\text{min}} = 0.5$, and $q_{\text{min}} \approx 1.0$ in Eq. (3), and $\Delta q_{\ell} = 0$, $\lambda = 6$, $\rho_0 = 0.75$, and $q_0 \approx 1.0$ in Eq. (4). Exceptions to these choices will be discussed as they occur. Examples of the hollow and low-shear profiles with the parameter choices defined above are plotted in Fig. 1 together with an example of the locally hollow profile with $\Delta q_{\ell} = 0.1$, $\lambda = 6$, $\rho_0 = 0.75$, $q_0 = 1.1$, $\rho_{\text{min}} = 0.5$, and $\Delta\rho = 0.1$.

The plasma geometry is given by specifying the major radius R_0 , the horizontal minor radius a_H , which is the distance from R_0 to the plasma boundaries on midplane, and a functional form for the plasma boundary. RSTEQ is a fixed boundary equilibrium code that maintains the specified boundary as the outside flux surface, so that $p = 0$ and $\psi_{\text{eq}} = \psi_{\text{eq}}(a)$ on the boundary. In this paper, we study the effects of plasma elongation and triangularity (D-shaping) on the $m = 1$ internal kink mode by using the following parameterization of the boundary:

$$R = R_0 + a_H \cos(\theta + \delta \sin \theta) \quad (5a)$$

and

$$z = \kappa a_H \sin \theta . \quad (5b)$$

In Eq. (5), z is the vertical coordinate, so that κ is the plasma elongation and δ is the triangularity. The maximum height of the boundary is $z_{\text{max}} = \kappa a_H$, which occurs at $R = R_0 - a_H \sin \delta$, so that $\sin \delta$ gives the inward shift of the maximum height (relative to a_H) caused by D shaping. Choosing $\delta = 0$ results in an elliptical plasma boundary, while $\kappa = 1.0$ and $\delta = 0$ give a circular plasma of radius a_H centered at R_0 .

The dynamical equations used here are those of MHD with an incompressibility assumption for the velocity

$$\vec{\nabla} \cdot \vec{v} = 0. \quad (6)$$

The magnetic field is represented in terms of the vector potential

$$\vec{B} = \vec{\nabla} \times \vec{A}, \quad (7)$$

which guarantees that \vec{B} is divergence-free. Similarly, the incompressibility assumption is enforced by using a vector stream function

$$\vec{v} = \vec{\nabla} \times \vec{\Phi} \quad (8)$$

to represent the velocity. The magnetic field is evolved by combining Faraday's and Ohm's laws to obtain an equation for the vector potential

$$\frac{\partial \vec{A}}{\partial t} = -\vec{\nabla} \alpha + \vec{v} \times \vec{B} - \frac{\eta}{S} \vec{j}, \quad (9)$$

where α is the electrostatic potential, $\vec{j} = \vec{\nabla} \times \vec{B}$ is the current, η is the resistivity, and $S = \tau_R/\tau_{Hp}$ is the Lundquist number. Both τ_R , the resistive skin time, and τ_{Hp} , the poloidal Alfvén time, are defined later in the discussion of the system of units for these equations. The velocity is evolved by taking the curl of the momentum equation, which eliminates the $\vec{\nabla} p$ pressure term and decouples the dynamics of the pressure from the momentum and magnetic field evolutions. Then, an evolution equation is obtained for the vector stream function

$$\frac{\partial}{\partial t} (\vec{\nabla} \times \vec{\nabla} \times \vec{\Phi}) = -\vec{\nabla} \times (\vec{v} \cdot \vec{\nabla} \vec{v}) + \vec{\nabla} \times (\vec{j} \times \vec{B}). \quad (10)$$

In obtaining Eq. (10), the mass density $\rho_m = \rho_{m0}$ is assumed to be constant in space and time. This assumption, together with Eq. (6), leads to satisfaction of the continuity equation

$$\frac{\partial \rho_m}{\partial t} + \vec{\nabla} \cdot (\rho_m \vec{v}) = 0. \quad (11)$$

In writing Eqs. (6)–(11), a system of units is used in which lengths are normalized to the generalized minor radius a , magnetic fields to the toroidal vacuum field B_0 at R_0 , mass density to the constant value ρ_{m0} , and resistivity to the value at the magnetic axis η_0 . In terms of these units, time is expressed in poloidal Alfvén times, $\tau_{Hp} = R_0/v_A$, where v_A is the Alfvén velocity, $v_A = B_0/\sqrt{\mu_0 \rho_{m0}}$, and μ_0 is the vacuum magnetic permeability. The resistive time, which then defines S , is given by $\tau_R = \mu_0 a^2/\eta_0$.

By eliminating the equation of continuity, only the two vector equations, Eqs. (9) and (10), must be evolved in time. Although it appears that this requires the solution of six dynamical equations, this number is reduced to five by an appropriate choice of gauge for the potentials \vec{A} and $\vec{\Phi}$. In terms of the flux coordinate representation, a gauge was chosen that had $A_\rho = 0$ and $\Phi_\rho = 0$, where A_ρ and Φ_ρ were the covariant ρ components of \vec{A} and $\vec{\Phi}$, respectively. Then, Φ_θ and Φ_ζ were obtained by solving the contravariant θ and ζ components of Eq. (10), thus giving $\vec{\Phi}$, and A_θ and A_ζ were obtained similarly to give \vec{A} using the covariant θ and ζ components of Eq. (9) with $A_\rho = 0$. Hence, closure of the incompressible full MHD equations involves the solution of five dynamical equations for α , A_θ , A_ζ , Φ_θ , and Φ_ζ for a three-dimensional perturbation plus an axisymmetric toroidal equilibrium in the magnetic flux coordinates of the equilibrium. The pressure perturbation does not enter the equations explicitly but can be calculated from the condition $\vec{\nabla} \cdot \vec{v} = 0$. The solution involves a finite difference representation in time and in the radial coordinate ρ , and Fourier series expansion is used in θ and ζ (for further details, see Refs. 13 and 14). For optimal numerical stability, the linear terms are advanced in time using a fully implicit technique, but the nonlinear terms are evaluated explicitly.

3. LINEAR STABILITY

Before discussing the nonlinear properties of the $m = 1$ instability associated with hollow and very flat profiles, it is important to analyze some of its linear properties. The linear stability properties for such profiles have been considered in the past in the large aspect ratio limit,^{16,17} and some stability results for low-aspect-ratio tokamaks were presented in Ref. 1. Here, those studies are expanded in some aspects that are important for the understanding of their nonlinear dynamics and also to incorporate shaping effects. Although the following linear studies involve ideal instabilities, the numerical calculations were carried out using $S = 10^7$ for the hollow profiles and $S = 10^5$ for the low-shear

profiles. Comparison with converged ideal growth rates for several cases indicates that the resistivities used do not significantly affect the results.

In Ref. 1 it was shown that the $m = 1$ mode dispersion relation for the case of hollow q profiles and circular cross section plasmas is

$$\bar{\gamma}^{2/3} (\bar{\gamma} + \delta q)^{1/3} = \frac{1}{(\rho_{\min}^2 q'')^{1/3}} (-\pi \epsilon^2 \rho_{\min}^2 \delta W_T)^{2/3}, \quad (12)$$

where $\bar{\gamma}^2 = 3(\gamma \tau_{H_p})^2 + (\delta q)^2$, $\delta q = q_{\min} - 1$, and γ is the linear growth rate. The general expression for δW_T up to fourth order in ϵ is given in Ref. 1 and contains the contribution to δW from the $m = 0$ and 2 components. For the particular q profile given in Eq. (3) at $\beta = 0$ and for both $\delta q \ll 1$ and $\Delta q \ll 1$, but large enough for the fourth-order δW to dominate over the sixth-order contribution, one has

$$\delta W_T = -\frac{\delta q}{4} - \frac{13}{96} \Delta q. \quad (13)$$

The dispersion relation in this case is

$$\bar{\gamma}^{2/3} (\bar{\gamma} + \delta q)^{1/3} = \left(\frac{\pi^2}{128} \right)^{1/3} (\rho_{\min} \epsilon)^{4/3} \frac{(\delta q + \frac{13}{24} \Delta q)^{2/3}}{\Delta q^{1/3}}. \quad (14)$$

In particular, for $\delta q = 0$ (i.e., for $q_{\min} = 1$), the dispersion relation simplifies further,

$$\gamma \tau_{H_p} \cong 0.163 (\rho_{\min} \epsilon)^{4/3} (\Delta q)^{1/3}, \quad (15)$$

showing the destabilizing effects of increasing toroidicity (ϵ) and the hollowness (Δq) of the profile. The stability threshold in δq for Δq fixed is not given by changing the sign of δW_T but by the increased field line bending. Therefore, the linear growth rate does not directly give a measure of the free energy available for the instability to grow. This is an important consideration when analyzing the nonlinear behavior of this mode. From Eq. (14) we can obtain a specific expression for this threshold value, $\delta q = \delta q_c$,

$$\delta q_c = 0.426 (\rho_{\min} \epsilon)^{4/3} \frac{(\delta q_c + \frac{13}{24} \Delta q)^{2/3}}{\Delta q^{1/3}}. \quad (16)$$

Results were shown in Ref. 1 for hollow safety factor profiles with $\Delta q = 0.1$ and $\rho_{\min} = 0.5$. The calculations were carried out with $\beta = 0$ and inverse aspect ratios in the range $0 < \epsilon \leq 0.4$ for varying q_{\min} . The numerical results show a sharp onset of ideal instability at $\delta q = \delta q_c$ with δq_c small and positive in agreement with Eq. (16). For $q_{\min} > 1 + \delta q_c$ the plasma is ideally stable, while for $q_{\min} < 1 + \delta q_c$ the plasma is unstable with growth rates rising sharply as q_{\min} is reduced below the stability boundary. For $\Delta q = 0.1$, these ideal growth rates peak in the vicinity of $q_{\min} \cong 1$. For $q_{\min} \geq 1$, the mode is ideally unstable and resistivity effects are very weak, so that even lowering S to 10^5 has practically no effect on the structure of the mode and its growth rates. Structurally the mode is an ideal $m = 1$ dominated, $n = 1$ internal kink with a large displacement vector in the plasma core (i.e., for $\rho \leq \rho_{\min}$). The numerical calculations show very good agreement with the analytic results of Eq. (14), exhibiting the $\epsilon^{4/3}$ scaling even down to values of $\epsilon \simeq 0.4$. We have also studied numerically, for circular cross section plasmas having $q_{\min} = 1.0$ and $\rho_{\min} = 0.5$, the dependence of the linear growth rate on the parameter Δq . In addition, some more general parameterizations, designed to fix the value $q_a = 1.9$ and affecting the q profile only for $\rho > \rho_{\min}$, were used, but the growth rates were insensitive to the changes associated with them. The dispersion relation, Eq. (15), shows that the linear growth rate should be proportional to $(\Delta q)^{1/3}$. Figure 2 plots the $n = 1$ linear growth rate as a function of $(\Delta q)^{1/3}$ for a sequence of hollow profile equilibria with Δq varying from 0.0005 to 0.5; the linear relationship between γ and $(\Delta q)^{1/3}$ is observed to be satisfied throughout this range. It is interesting to observe how well the large aspect ratio analytic calculations are satisfied in this tight aspect ratio ($\epsilon = 0.4$) regime.

Behavior of the numerically calculated growth rates as a function of δq for fixed values of $\Delta q = 0.1$ and 0.01 is compared with that predicted by the dispersion relation, Eq. (14), in Fig. 3. For $\delta q = 0$ ($q_{\min} = 1.0$), the numerical and analytic expressions agree quite

closely. For $\delta q > 0$, the analytic and numerical calculations both lead to similar qualitative behavior. Quantitatively, however, the curves differ for increasing δq . For values of Δq less than 0.01, the discrepancy increases, but for low shear, the fourth-order term in δW is no longer dominant, and it is necessary to retain sixth order in the expansion. The quantitative differences between the analytic and numerical growth rate calculations here are not surprising because the analytic results are based on an $\epsilon \ll 1$ expansion, and here $\epsilon = 0.4$ is used. At large aspect ratio ($\epsilon = 0.1$ for example), close quantitative agreement is obtained for all δq .¹

The effect of plasma pressure on the $n = 1$ kink mode is shown for the hollow and low-shear profiles in Fig. 4. Both cases were calculated using a circular cross section with $\epsilon = 0.4$ and the pressure profile of Eq. (2). Equation (3) was used for the hollow profile with $q_{\min} = 1.0$, $\Delta q = 0.1$, and $\rho_{\min} = 0.5$, while Eq. (4) was used for the low-shear profile with $\Delta q_{\ell} = 0$, $q_0 = 1.0$, $\lambda = 6$, and $\rho_0 = 0.75$. Figure 4 shows that, although the linear growth rates increase with β for both q profiles, the basic difference between the stability properties is the instability of the hollow profile equilibria at $\beta = 0$ and the marginal stability of the low-shear profile at $\beta = 0$. For $n > 1$, the modes are found to be stable at $\beta = 0$ for both hollow and low-shear profiles. However, as β is increased these higher n modes are destabilized as shown at $\beta_0 = 2\%$ in Fig. 5 for the same equilibria as studied in Fig. 4. For $n \leq 8$, the growth rate curves show a peak and then a leveling off for the low-shear profile, but the hollow profile growth rates show a slow linear increase with n . The discontinuity of the curve at $n = 1$ for the hollow profile reflects the different character of that mode, which is unstable at $\beta = 0$. Hence, for both types of q profile, higher $n > 1$ pressure-driven modes are destabilized when $\beta \neq 0$.

Now consider, for varying safety factor profiles, the effect of plasma cross section shape on the stability of the $m = 1$ mode. The method used here will be to study sequences of equilibria of various shapes, with each sequence determined by a single $q(\rho)$ profile. Therefore, because of shape effects, the average current $J(\rho)$ changes within each sequence, and

this brings about changes in both the driving terms and the field line bending. In addition to these changes, noncircularity introduces additional couplings between the poloidal components, and these couplings also affect the stability of the modes. It is important to understand and separate these effects.

To do this, first consider, for the hollow profile [Eq. 3] with $q_{\min} = 1.0$, $\rho_{\min} = 0.5$, and $\Delta q = 0.1$, the effect of elongating the plasma. In the case of no triangularity, $\delta = 0$, Fig. 6a shows the $n = 1$ linear growth rate as a function of the elongation κ for a sequence of equilibria having $\beta = 0$. The three curves correspond to fixed $\epsilon_H = 0.4$, fixed $\epsilon = 0.4$, and fixed $\epsilon_H = 0.4$, but they include only three poloidal components in the stability calculation. Although most calculations in this paper are carried out at fixed $\epsilon_H = 0.4$, which will be the case unless stated otherwise, the fixed ϵ curve was calculated here to illustrate the difference for elongated plasmas. Also, unless stated otherwise, all calculations in this paper are carried out with a sufficient number of poloidal components to give converged growth rates. The purpose of calculating the curve containing only three components [the dominant (1;1) and the toroidally coupled (0;1) and (2;1) sidebands] is to separate the effects of the elongated equilibrium from those of the mode coupling caused by elongation. These latter couplings involve the (1;1) harmonic and the twice-removed (-1;1) and (3;1) sidebands, although, for the low aspect ratio considered, the separation between these effects is less obvious. The three-component curve for fixed ϵ_H shows that, for this profile, the effect of the changing equilibrium on growth rates is initially a mild destabilization, followed by stabilization as the elongation is increased. The effect of the elongation-induced couplings is stabilizing, as can be seen by comparing the three-component and converged curves for fixed ϵ_H . Note that for all these cases ($q \geq 1$) the coupling effect is opposite that for the internal kink with monotonic q profile and $q < 1$ in the plasma core.^{18,19} This procedure has been carried out for cases having $q_{\min} > 1$, and again the elongation-induced couplings are found to be stabilizing. The converged curve shows that, for this particular equilibrium sequence, the overall effect of elongating the plasma is one of stabilization.

Comparing the linear growth rates obtained at fixed ϵ with those at fixed ϵ_H shows that, for given elongation, the fixed ϵ growth rates are smaller than those at fixed ϵ_H . This comparison can be clarified by examining the growth rates for each elongation in terms of the similarly defined aspect ratio because this is the only quantity that differs between the two curves. Figure 6b shows, for each elongation tested, the growth rates from the constant ϵ and constant ϵ_H curves plotted versus $\epsilon^{4/3}$ together with lines from the points through the origin. Clearly the difference between the constant ϵ and constant ϵ_H curves in Fig. 6 is the $\epsilon^{4/3}$ aspect ratio dependence of the growth rate. Except at $\kappa = 2$, where the growth rates are very small and difficult to calculate accurately, the values of $\gamma/\epsilon^{4/3}$ for the constant ϵ and constant ϵ_H curves are found to agree to within 5%, and even at $\kappa = 2$ the agreement is within 20%.

Now consider, for the same hollow profile used before, the effects of triangularity for fixed $\epsilon_H = 0.4$, $\beta = 0$, and κ (Fig. 7). The two curves in this figure are for $\kappa = 1.0$ and $\kappa = 1.6$. The $\kappa = 1.0$ curve shows, in qualitative agreement with analytical calculations, that triangularity destabilizes the internal kink for these hollow profiles. For $\kappa = 1.6$ the effect is also destabilizing and is stronger than the effect for $\kappa = 1.0$. Indeed, this effect is strong enough to overcome the stabilizing effect of ellipticity. Thus, if κ and δ are varied simultaneously to go from a circular shape to one having $\kappa = 1.6$ and $\delta = 0.3$, the overall effect is destabilizing rather than stabilizing.

The destabilizing effect of triangularity comes mostly from its effect on the equilibrium. To illustrate this result, we have plotted in Fig. 8a the $n = 1$ linear growth rate versus the number of poloidal components used in the calculation for the hollow profile for three different plasma shapes: a circle ($\kappa = 1.0$, $\delta = 0$), a triangular case without elongation ($\kappa = 1.0$, $\delta = 0.5$), and a triangular case with elongation ($\kappa = 1.6$, $\delta = 0.3$). In all three cases, a much stronger growth rate is obtained by using three components, (0;1), (1;1), and (2;1), rather than a single one (1;1). Because (0;1) and (2;1) provide the basic toroidal coupling to (1;1), this shows the necessity of treating these cases properly in toroidal geometry by

including the necessary toroidal couplings. The five-component results include elongation-induced couplings $[(-1;1)$ and $(3;1)]$ in addition to the basic toroidal coupling, and these are seen to be stabilizing. The greatest stabilization is obtained for the elongated case, $\kappa = 1.6$, while the $\kappa = 1$ cases are only slightly affected. In passing to seven components, the triangularity-induced couplings $[(-2;1)$ and $(4;1)]$ to the $(1;1)$ mode are introduced, and these dynamical couplings are seen to be very slightly destabilizing for the cases with $\delta \neq 0$. In all three cases, these seven-component results are essentially converged. For nonelongated plasmas, the three-component growth rates are within 5% of the converged values, and the dynamical effects of the additional shape-dependent couplings are slight. For elongated plasma, the elongation-induced coupling is significantly stabilizing, but in all cases the triangularity-induced couplings show only a slight destabilizing effect. Hence, the overall destabilization caused by triangular plasma shaping, which was observed in Fig. 7, is mainly an effect of the equilibrium properties.

At this point it is useful to introduce some energy-like quantities, which are defined as follows:

$$E^v = \sum_{\substack{(m;n) \\ \neq (0;0)}} \left(E_{(m;n)}^{\Phi_\theta} + E_{(m;n)}^{\Phi_c} \right) \quad (17)$$

and

$$E^B = \sum_{\substack{(m;n) \\ \neq (0;0)}} \left(E_{(m;n)}^{A_\theta} + E_{(m;n)}^{A_c} \right), \quad (18)$$

where, for any field f ,

$$E_{(m;n)}^f = \int \left[\left(\frac{\partial f_{(m;n)}}{\partial \rho} \right)^2 + \left(\frac{1}{\rho} \frac{\partial f_{(m;n)}}{\partial \theta} \right)^2 \right] d\tau, \quad (19)$$

with the summations taken over all components except $(m;n) = (0;0)$ and the volume integration taken over the entire plasma. Figure 8b plots the magnetic field norms

$E_{(m;n=1)}^B = E_{(m;n=1)}^{A\theta} + E_{(m;n=1)}^{A\zeta}$ versus m for the eigenfunctions of the three cases considered in Fig. 8a. The structure of these plots clearly shows the effects of cross section shape. In particular, the norms for the circular cross section case decay monotonically moving away from $m = 1$. The elongated case shows secondary peaks at $m = -1$ and $m = 3$; for the triangular case, secondary peaks occur at $m = -2$ and $m = 4$. It is interesting that similar plots of the velocity norms $E_{(m;n)}^v = E_{(m;n)}^{\Phi\theta} + E_{(m;n)}^{\Phi\zeta}$ show little effect of changing the cross section shape. For all three cases, the values decay monotonically away from the peak at $m = 1$, and the results for the three curves are in close agreement.

We now study for several shapes the behavior of linear growth rate as a function of q_{\min} with the safety factor profile otherwise fixed as above with $\Delta q = 0.1$ and $\rho_{\min} = 0.5$ in Eq. (3). Figure 9 shows this dependence for plasmas having $\delta = 0$ and $\kappa = 1.0, 1.4, 1.6$ and 2.0 as well as for $\kappa = 1.6, \delta = 0.3$. Figures 6a ($\epsilon_H = 0.4$) and 7 give the $q_{\min} = 1.0$ results shown here. Note that, as q_{\min} is increased above 1.0, the growth rate achieves a maximum value, except for the circular cross section case for which the maximum is at q_{\min} somewhat less than 1.0. The maximum growth rate is quite close to the value obtained at $q_{\min} = 1.0$, and for further increases in q_{\min} , the growth rate drops at first gradually and then quite sharply near the stability boundary. For these cases, larger values of q_{\min} at the stability boundary correspond to larger growth rates at $q_{\min} = 1.0$ (i.e., the curves are enveloped and do not cross). Hence, for several shapes, including elongation and triangularity, the dependence of the linear $n = 1$ growth rates for the ideal internal kink as a function of q_{\min} is similar to that found earlier¹ for a circular cross section displaying, in particular, a very sharp stability boundary. It is also important to note that changes in shape can produce sudden onset of the instability. Figure 9 shows that decreasing the elongation or increasing the triangularity for fixed profile with $q_{\min} > 1$ can change the plasma from stable to unstable.

As for the stability of the zero-shear profiles, some results were presented in Ref. 1 for the q profile given in Eq. (4). In that paper, $\Delta q_\ell = 0$, $\lambda = 6$, and $\rho_0 = 0.462$ (we use

$\rho_0 = 0.75$ here) were used for circular cross section plasmas with varying q_0 and β . In this case, the ideal $n = 1$ linear eigenfunctions are pressure driven and stable at $\beta = 0$ for q_0 above 1. The stability is marginal at $q_0 = 1$, and as β is increased an unstable ideal mode is found. This is shown in Fig. 4, which contrasts the β dependence of the $n = 1$ linear growth rates for the low-shear and hollow profiles. As with the hollow profile, the finite β mode demonstrates a sharp stability boundary at $q_0 = 1 + \delta q_c$ for q_0 slightly above unity. Below this value is an $n = 1$ instability. For $q_0 \geq 1$, the growth rate and structure of the mode are fairly independent of resistivity, and the mode is ideally unstable. Structurally the mode is $m = 1$ dominated with a large displacement vector in the plasma core; Wesson refers to this instability as a quasi-interchange mode.⁹

We have studied, for these essentially shearless profiles, the effects of shaping and profile variation. The results presented here were calculated at inverse aspect ratio $\epsilon_H = 0.4$ and peak plasma beta $\beta_0 = 2\%$. The pressure profile of Eq. (2) was used together with the safety factor profile of Eq. (4) with $\Delta q_\ell = 0$, $\lambda = 6$, and $\rho_0 = 0.75$. In Fig. (10a) the $n = 1$ linear growth rates are plotted as functions of q_0 for shaped plasmas having no triangularity, $\delta = 0$, and elongation $\kappa = 1.0, 1.2, 1.4$, and 1.6 . Note that in all cases the growth rate curves peak at some value of $q_0 > 1$ and then decrease to zero at somewhat larger q_0 . The effect of the elongation is to shift the peak and upper stability boundary to higher values of q_0 . Values of the peak growth rates at first increase and then decrease with increasing elongation. An analysis of the couplings in terms of components shows behavior similar to that observed for hollow profiles in Fig. 8. The addition of the $(-1;1)$ and $(3;1)$ components, which are coupled to the $(1;1)$ by elongation effects, reduces the linear growth rate significantly from that obtained using three components. A combination of these stabilizing couplings and the effects of the elongated equilibrium determines the overall effect on the stability of the mode. Figure 10b shows that adding triangularity to the plasma cross section destabilizes the $n = 1$ mode, both for circular and elongated plasmas. As for the hollow profiles, this destabilization can be shown to be caused by the

change of equilibrium. The addition of the triangularity-coupled $(-2;1)$ and $(4;1)$ modes has little effect on growth rates, which are essentially converged using five components; thus, the triangularity-induced couplings have little influence.

The effects of cross section elongation on the $n = 1$ mode are contrasted for the hollow and low-shear profiles in Fig. 11. The parameterizations of Eqs. (3) and (4) were used with $\Delta q = 0.1$ and $\rho_{\min} = 0.5$ in Eq. (3) and $\lambda = 6$, $\rho_0 = 0.75$, and $\Delta q_\ell = 0$ in Eq. (4). The cases shown were for no triangularity, $\delta = 0$, and horizontal inverse aspect ratio $\epsilon_H = 0.4$. For the hollow profile cases, increasing either q_{\min} or the elongation, κ , tends to stabilize the mode. These instabilities were calculated for equilibrium values of $\beta = 0$. For the low-shear equilibria, $\beta_0 = 2\%$ was chosen. In these cases, elongating the plasma at first destabilizes the mode, leading to a peak in the growth rate curve beyond which further elongation stabilizes the mode. Increasing the value of q_0 leads to different curves for which the instability is transferred to higher elongations. Hence, the effects of elongation on these two types of instability are basically different.

The sensitivity of the linear stability, the driving forces, and the growth rates of the $n = 1$ mode to small changes in the safety factor profile should be apparent. As a final illustration of this sensitivity, consider the transition from very low shear to hollow safety factor profile given by varying q_0 and Δq_ℓ in Eq. (4) with fixed $\lambda = 6$, $\rho_0 = 0.75$, $\rho_{\min} = 0.5$, and $\Delta\rho = 0.1$. These parameters superimpose on the low-shear profile just discussed a local minimum of depth Δq_ℓ and width $\Delta\rho$ centered at ρ_{\min} , and for $\Delta q_\ell = 0$ the low-shear profile is obtained. For $q_0 = 1.1$ and $\Delta q_\ell = 0.1$, this profile is compared with the hollow and very low shear profiles in Fig. 1. For these calculations, we choose $\epsilon_H = 0.4$ and $\beta_0 = 0$ and 2% as above and a plasma shape ($\kappa = 1.6$, $\delta = 0.3$). The linear stability results of this study are presented in Fig. 12. Figure 12a shows the $n = 1$ linear growth rate as a function of q_0 , both with $\Delta q_\ell = 0$ (no local minimum) and with $\Delta q_\ell = q_0 - 1$ (a local minimum of $q_{\min} \approx 1$). For the flat profile without local minimum, the result at $\beta_0 = 2\%$ is as shown in Fig. 10b, with a stability boundary at $q_0 = 1.03$ and a peak growth rate at $q_0 = 1.015$. At

$\beta_0 = 0$, this pressure-driven mode is stable. Although the linear growth rate at $\beta_0 = 2\%$ is not extremely different for the hollow profile when $q_0 \lesssim 1.015$, for values above this the hollow profile becomes increasingly unstable, while the low-shear profile is stabilized. Hence, as q_0 is increased with $q_{\min} = 1.0$, comparison with the low-shear profile shows that the local hollow nature leads to destabilization. Carrying out the same sequence of calculations for the locally hollow profile with $\beta = 0$ and $q_{\min} = 1.0$ shows an increase in linear growth rate from marginal at $q_0 = 1$ as q_0 increases. To further illustrate this sensitivity, Fig. 12b plots the $n = 1$ linear growth rate as a function of $q_{\min} \approx q_0 - \Delta q_\ell$ for $q_0 = 1.03$ (marginally stable for $\Delta q_\ell = 0$) and $q_0 = 1.04$. Both cases become unstable, with similar rapidly increasing growth rate curves, as q_{\min} is decreased below the boundary at 1.03. Hence, small local changes in the safety factor profile can trigger robust ideal $n = 1$ instabilities with linear growth rates around $10^{-2} \tau_{Hp}^{-1}$.

4. NONLINEAR EVOLUTION OF THE INTERNAL KINK

To understand the dynamics of the internal kink evolution, numerical calculations have been carried out for a variety of profiles and plasma shapes. To limit the considerations to ideal kinks, only q profiles with $q(\rho) \geq 1$ have been considered. Some of the properties of the nonlinear evolution are common to all profiles and shapes considered. Let us begin by describing the general properties of the nonlinear evolution of the $m = 1$ internal kink mode. Although the calculations studied here involve ideal instabilities, the nonlinear calculations are carried out using $S = 10^5$.

For a general description of the properties of the nonlinear evolution let us consider a case with $q(\rho) > 1$. Figure 13 shows the evolution of the velocity norm for a small initial perturbation of an equilibrium having $\epsilon_H = 0.4$, $\beta_0 = 2\%$, $\kappa = 1.6$, $\delta = 0.3$, and a safety factor given by Eq. (4) with $\Delta q_\ell = 0$, $q_0 = 1.015$, $\rho_0 = 0.75$, and $\lambda = 6$. The linear growth rate for this case is $\gamma \approx 10^{-2} \tau_{Hp}^{-1}$. The time scale for the evolution is essentially γ^{-1} for $t \lesssim 400 \tau_{Hp}$, as can be seen from the exponential growth of E^v with an e -folding

time of about $50\tau_{H_p}$. After $400\tau_{H_p}$ nonlinear effects lead to a saturation of the instability, with E^v peaking at $t = 600\tau_{H_p}$. Figure 14 shows vector plots of the velocity in the $\zeta = 0$ plane, which reveal a dominant $m = 1$ convective motion throughout the plasma core. Because the instability is ideal and evolving rapidly, we expect the magnetic field to be carried by the convective motion illustrated here. The times of the plots are indicated by the arrows in Fig. 13. The initial plot, taken at $t = 600\tau_{H_p}$, shows a convective motion, which, in this plane, should transport the central plasma and magnetic field to the right. Subsequent plots at $t = 752\tau_{H_p}$ and $t = 947\tau_{H_p}$, when taken together with the velocity norm of Fig. 13, show the saturation, decrease, and reversal with smaller amplitude of this motion. Figure 15 illustrates the effect of the instability on the magnetic field configuration by plotting the magnetic surfaces in the $\zeta = 0$ plane. At $t = 600\tau_{H_p}$, the time of peak saturation of the instability, the plasma core has been shifted to the right (for $\zeta = 0$) by the convective motion, shown in Fig. 14. In comparison with equilibrium, the magnetic axis has been shifted $x = 0.25$ to the right on the horizontal scale. The subsequent field line plots at $752\tau_{H_p}$ and $947\tau_{H_p}$ show no further change in the shift of the magnetic axis, a behavior in keeping with the saturation of the instability, which will be examined in detail later. However, the shape of the shifted core continues to change in response to the velocity field of the instability, becoming somewhat more crescent shaped at later times. Although the shift generated by the instability is shown to be outward in the $\zeta = 0$ plane (Fig. 15), the $m/n = 1/1$ helical nature of the instability is manifested by examining the magnetic surfaces in several poloidal planes (Fig. 16). The plots in Fig. 16 were taken from a different case having a hollow profile and $q_{\min} = 1.0$, which leads to the magnetic bubble to be discussed later, but the $m/n = 1/1$ helical behavior is quite general to all these cases. The total evolution is governed by ideal MHD, as is the time scale, and the magnetic field line topology remains unchanged.

Let us now consider two cases in which $q \geq 1$, with $q = 1$ at one radial position. As a first example, we take the case of a hollow q profile with $q_{\min} = 1$. Figure 17 shows

the magnetic field line plots at four different times for the evolution of a small initial perturbation of a circular cross section equilibrium with $\epsilon_H = 0.4$, $\beta = 0$, and the q profile parameters $\Delta q = 0.1$, $\rho_{\min} = 0.5$, and $q_{\min} = 1.0$ in Eq. (3). The nonlinear evolution of the instability is consistent with the one given earlier, but now an additional topological feature is caused by the presence of a $q = 1$ surface. The initial perturbation of the equilibrium has changed the topology such that a new magnetic axis appears close to the $q = 1$ surface. The new magnetic surface structure is different than the one created by a tearing mode. The nonlinear evolution does not resemble the growth of a magnetic island but is more reminiscent of the nonlinear evolution of a vacuum magnetic bubble.²⁰ Although other aspects of the evolution, particularly the shift and subsequent crescent shaping of the core because of the $m = 1$ convective motion, are unaffected by the presence of the magnetic bubble, the details of the evolution pertaining to the bubble could be affected by the value of S .

Another special case occurs when q is very close to unity throughout most of the plasma core. Such cases include the low-shear profiles when $q_0 \approx 1$ and also the hollow profiles when $\Delta q \ll 1$. Consider, for example, the case depicted by the field line plots in Fig. 18. In this example, the low-shear q profile of Eq. (4) is used with $\Delta q_\ell = 0$, $q_0 = 1.0$, $\rho_0 = 0.75$, and $\lambda = 6$ for a circular cross section plasma having $\epsilon_H = 0.4$ and $\beta_0 = 2\%$. For this profile, the rate of increase in q throughout the plasma core is so slow that q changes from 1.0 at $\rho = 0$ to 1.0013 at $\rho = 0.5$. Figure 18 shows that the penetration of the outside plasma into the center is more pronounced for this case, as is the crescent formation by the shifted plasma core, than for cases having larger q through most of the core. In this case, the plasma core is essentially a large $q = 1$ region. The high n modes, which are linearly unstable for this case, play a more important role, and distortion of the magnetic surfaces is characterized by m modes higher than $m = 1$. Despite the existence of unstable high n modes of the 1/1 helicity, we have observed no nonlinear acceleration effects in any of the cases studied.

Let us now consider some systematics of the evolution. We focus on a sequence of equilibria having $\epsilon_H = 0.4$, a circular cross section, $\beta = 0$, and a hollow q profile ($\rho_{\min} = 0.5$, $\Delta q = 0.1$) with q_{\min} varying between 1.0 and 1.02. The linear growth rates for this sequence are plotted in Fig. 9 ($\kappa = 1.0$, $\delta = 0$ curve). They reach a maximum for $q_{\min} = 1.0$, and the marginal stability equilibrium is at $q_{\min} = 1.018$. The saturation level of the instability-induced flow velocity increases as q_{\min} goes from 1.015 to 1.0. This is shown in Fig. 19a, where the velocity norm is plotted as a function of time for several values of q_{\min} ; in all cases, near exponential growth is followed by saturation. As saturation is reached, the 1/1 component of the velocity reverses. This can be seen in Fig. 19b, where the maximum of the (1;1) component of Φ_θ (the θ component of the velocity stream vector) is plotted versus time for each of the cases considered. The curves have been shifted in time in Fig. 19b to give equal initial values of Φ_θ^{\max} . The peaks in Φ_θ^{\max} correspond closely in time to those for E^v in Fig. 19a. The magnetic axis shifts as the instability grows, as shown in Fig. 17 for the particular case with $q_{\min} = 1.0$. The saturation of the axis shift is simultaneous with the velocity reversal, as should be expected for an ideal instability. Figure 20 shows this result for the case of $q_{\min} = 1.0$. The saturated axis shift decreases as q_{\min} increases toward the marginal stability point $q_{\min} = 1.018$. Figure 21 shows the corresponding magnetic field line plots of the saturated instabilities for the four values of q_{\min} ; note that the shifts decrease as q_{\min} increases toward the stability boundary. The value of the magnetic axis shift is correlated with the total fluid displacement. To estimate this displacement, we multiply the peak value of Φ_θ^{\max} by $1/\gamma_{n=1}$, the inverse of the $n = 1$ linear growth rate for each case (Fig. 9), which is proportional to the time over which the instability acts. The correlation between the magnetic axis shift and $\Phi_\theta^{\max}/\gamma_{n=1}$ is shown in Fig. 22. After saturation, Φ_θ^{\max} changes abruptly (Fig. 20), changing its sign in the process, so that the flows are reversed. This change in velocity flow behavior can also be seen in the velocity vector plots (Fig. 14), and it is responsible for the change in the shape of the flux surfaces, which increase their crescent shape after saturation.

In concluding this section, we note that the effects of cross section shaping and plasma β are less pronounced than the sharp sensitivity to profile variations. Even at $\beta = 0$, where the low-shear profiles are linearly stable, very slight local changes can hollow such profiles and lead to destabilization. Neither changes in plasma pressure nor variations in cross section shape have been found to significantly affect the earlier description of the nonlinear evolution of the $m = 1$ instability. For example, the case considered in Figs. 13–15 was calculated for an equilibrium having $\kappa = 1.6$, $\delta = 0.3$, and $q_0 = 1.015$ in Eq. (4) which falls at the peak of the corresponding linear growth rate curve in Fig. 10b. Calculations for circular cross section, made at $q_0 = 1.005$ or 1.01 to fall well within the unstable region of the corresponding mode, evolve in keeping with the earlier description. The hollow profile cases shown in Figs. 16 and 17 differ only in the shape of the plasma cross section, and again in both cases the evolution fits the earlier description including the magnetic axis shift, saturation, and magnetic bubble formation. Calculations like that depicted in Fig. 17, but at $\beta \neq 0$, show this same process. Although details such as time scales (which are dependent on the values of linear growth rate), saturation levels of the norms, or the exact parameter values for the profiles differ with β and cross section shape, the overall description of the nonlinear process is not crucially shape or, for hollow q , β dependent.

5. NUMERICAL CONSIDERATIONS

References 13 and 14 discuss the numerical scheme used in these calculations, and other publications have considered some of the problems regarding numerical convergence of the nonlinear calculations.^{21–24} The particular calculations presented here are rather benign, in that they are almost single-helicity dominated. However, we will now discuss the numerical aspects of the calculations that are directly relevant to the results of Sect. 4.

Although the nonlinear process described in this section is dominated by ideal MHD, the numerical calculations include explicit dissipation terms, apart from the dissipation

induced by a finite-size grid. In particular, resistivity is nonzero and a value of $S = 10^5$ is included. As stated before, for profiles with $q \geq 1$ the resistivity has little effect on the linear structure and growth rates of these ideal instabilities. Typically, at $S = 10^5$ the linear growth rates are within a few percent of the ideal values and the eigenfunctions are visibly indistinguishable from the ideal ones. Nonlinearly, it is therefore expected that the observed evolution will be ideally determined, with the value of the resistivity affecting only the long-term behavior through reconnection. By repeating some of the nonlinear calculations with different values of S , we have confirmed the independence of the dynamics of the nonlinear evolution from the resistivity.

For numerical stability of the nonlinear evolution, we have also found it necessary to include a small ion viscosity in the momentum equation. Typically a constant value of $\nu/S = 10^{-6}$, which is small enough not to affect the linear growth rates, is used. Numerical tests, using different values of the viscosity in repeating nonlinear calculations, have been performed. As with the resistivity tests, the independence of the dynamical evolution from the viscosity has been demonstrated.

For low-shear profiles at nonzero β values, some of the high n modes are linearly unstable (Fig. 5), and they have a visible effect on the nonlinear evolution of the flux surfaces (Fig. 18). Therefore, it is important to discuss the mode spectrum used in the nonlinear calculations. The mode selection we have used for most of the nonlinear calculations includes 32 components: $(m = -2 \rightarrow 4; n = 1)$, $(m = 0 \rightarrow 4; n = 2)$, $(m = 2 \rightarrow 5; n = 3)$, $(m = 3 \rightarrow 5; n = 4)$, $(m = 4 \rightarrow 6; n = 5)$, $(m = 6; n = 6)$, $(m = 7; n = 7)$, and $(m = 0 \rightarrow 7; n = 0)$. To assess the effect of these higher n modes on the nonlinear evolution, the calculation for the case shown in Fig. 18 was carried out both for the usual 32-mode set defined above and for 44 modes in which the (1;3), (2;4), (6;4), (3;5), (7;5), (4;6), (5;6), (7;6), (8;6), (6;7), (8;7), and (8;8) components were added. The evolution of the overall velocity norm E^v for both calculations is shown in Fig. 23 together with that of $E_{(5;5)}^v$ and $E_{(6;6)}^v$ from the 44-mode calculation. It is apparent that up through and beyond

the saturation the two calculations are in good agreement and that $E_{(5;5)}^v$ and $E_{(6;6)}^v$ remain small. Figure 24 plots the spectra of the velocity norms at $t = 1100\tau_{H_p}$ (saturation) and $1350\tau_{H_p}$. The results at $1100\tau_{H_p}$ show close agreement up to about $n = 5$, at and above which the 44-mode results are larger than those obtained using 32 modes. For $n = 6$ and $n = 7$, this is probably caused by inclusion of the toroidal curvature effects through the couplings to the satellite modes. As seen earlier for $n = 1$ (Fig. 8a), these couplings enhance the linear growth rates. We also note that the magnitudes of these high n velocity norms are small, in both cases, compared with those for lower n , and that for each n the peak is in the 1/1 helicity; therefore, in addition to the linear growth for each n mode, nonlinear driving from other n modes is significant, particularly in the 1/1 helicity. Figure 24b, taken at $1350\tau_{H_p}$, shows greater differences between the two calculations, with the first occurrence at $n = 2$. For both calculations, especially the 32-mode case, the higher n velocity spectra have become flat, and a higher number of modes would be necessary to represent well the long-time behavior. However, the $n = 1$ peaks and the overall velocity norms are still in reasonable agreement for both cases, so that the differences in the high n evolution for the two cases have not significantly affected the global evolution (i.e., shift) at this time, nor has the overall saturation level been affected. An analysis of the mode spectrum for a hollow profile case at $\beta = 0$ [using a more general parameterization described in Eq. (22)] indicates that 32 components are sufficient to describe the evolution to saturation ($t = 1300\tau_{H_p}$), during which the $n = 1$ mode is dominant (Fig. 25a). At later times ($t = 1600\tau_{H_p}$), however, the $n = 1$ velocity norm decreases while the higher n modes increase, thus flattening the spectrum (Fig. 25b); to consider the detailed evolution at these later times would require additional modes.

6. DISCUSSION

The nonlinear calculations show that the saturated axis shift does not correlate with the linear growth rate, which is not surprising. The saturation axis shift will depend on the

mechanism of nonlinear saturation. In this particular case, it seems that the mechanism is the increased field line bending generated by the shift of the plasma. In the equilibrium flux coordinate system, the nonlinear evolution changes the profile by an amount $(\delta\tilde{q})$. This change has to be such that in the flux coordinate system of the final state the q profile has not changed (the nonlinear evolution is ideal). This gives the relation

$$\frac{\Delta}{a} \approx \sqrt{\frac{16(\delta\tilde{q})}{q''}}. \quad (20)$$

At saturation, $(\delta\tilde{q})$ has to be equal to the change of q required to stabilize the mode; that is, for the hollow q profile, $(\delta\tilde{q}) = \delta q_c - \delta q$. For the hollow q profile given by Eq. (3), this implies

$$\frac{\Delta}{a} \approx \rho_{\min} \sqrt{2 \frac{\delta q_c - \delta q}{\Delta q}}. \quad (21)$$

An analytic calculation of the saturated displacement²⁵ gives the result

$$\left(\frac{\Delta}{a}\right)^2 \frac{q''}{\delta q} = \frac{8}{71} \left(\frac{8\pi}{3}\right)^2 \left[\left(\frac{\delta q_c}{\partial q}\right)^{3/2} - 1 \right] \quad (22)$$

in the limit $(\delta q_c - \delta q)/\delta q < 1$. In this calculation the nonlinear field line bending effects are found to be more important within the layer at q_{\min} than elsewhere. The helical equilibrium equation is solved in the layer (subject to accessibility conditions) and matched to the outer regions on either side. Equation (22) agrees in form with Eq. (20) and, because the calculation of Ref. 25 is asymptotically rigorous, shows that the numerical constant inside the square root is 11.86.

In Fig. 26, the saturated axis shift has been plotted versus $(\delta q_c - \delta q)$ for several of the cases studied. First consider the sequence of hollow profile equilibria, which were discussed in detail in Sect. 4 (Figs. 18–22). The predicted shift for this sequence (for which $\Delta q = 0.1$ and $\delta q_c = 0.018$) is given according to Eq. (20) by a solid straight line and according to Eq. (22) by the dashed curve in Fig. 26. Both analytic expressions are found to agree

reasonably well with each other and with the results of the numerical calculations. Also shown on Fig. 26 are the equivalent data for two cases having the same q profile, $\epsilon_H = 0.4$ and $\beta = 0$, but with elongation $\kappa = 1.6$ and triangularity $\delta = 0.3$. Figure 9 shows that for this cross-sectional shape, $\delta q_c = 0.027$, and the two cases shown have $\delta q = 0$ and 0.01. Estimates of the shift and the minor radius for this case are complicated by the noncircularity of the plasma cross sections. For the circular plasma sequence, magnetic field line plots in different poloidal planes show that the magnetic axis describes a circular helical path so that the poloidal projection of this orbit is a circle. For the noncircular cases, this projection is also noncircular, and the plotted points are for the maximum shift normalized to the generalized minor radius. Therefore, the critical parameters for understanding the nonlinear dynamics are the field line bending term and the details of the q profile. The results do not indicate any strong sensitivity to the shaping except that the shaping modifies the equilibrium. In this sense, the inclusion of toroidicity and shaping has qualitatively not changed the conclusions of Refs. 9–11, where the nonlinear calculations were limited to circular cross section cylindrical geometry.

Sensitivity to the q profile provides a potential explanation of the rapid sawtooth crash, which appears on large tokamaks. The crash is called rapid because the observed time for the event is much less than the predicted reconnection time using the Kadomtsev model. For example, on JET the rapid crash takes typically 100 μs , or about $500\tau_{H_p}$, while the Kadomtsev prediction of 5 ms is a factor of 50 greater than the observed value.⁴ The observed crash time of $500\tau_{H_p}$ is commensurate with the nonlinear evolution times of the cases considered in this work, which were calculated using the geometric parameters of JET. Furthermore, it has been experimentally observed,² using X-ray tomography, that the hot plasma core is helically shifted and then distorted into a crescent during the crash. This also is consistent with the nonlinear evolution studied here. An important question concerns how this rapid process can be suddenly triggered. This implies that we must have $\delta q_c - \delta q$ such that $\gamma_{n=1}^{-1} \approx 500\tau_{H_p}$, and $\Delta/a \approx 0.2$; given the slow rate of profile change,

$\delta q_c - \delta q$ must be small to be compatible with the fast trigger. By looking at Eqs. (14) and (21), we see that reducing Δq could be a way of achieving the types of profiles that could be compatible with experimental data. To do that, we use the more complicated q profile parameterization

$$q(\rho) = \begin{cases} q_{\min} + \Delta q_{\text{in}} \left[1 - \left(\frac{\rho}{\rho_{\min}} \right)^2 \right]^2 & \text{for } \rho \leq \rho_{\min} \\ q_{\min} + \Delta q_{\text{out}} \left[1 - \left(\frac{\rho}{\rho_{\min}} \right)^2 \right]^2 & \text{for } \rho \geq \rho_{\min} \end{cases}, \quad (23)$$

which permits the reduction of q'' at ρ_{\min} while keeping constant $q = q_a$ at the plasma edge. By choosing $\Delta q_{\text{in}} = 0.003$, the maximum growth rate is $\gamma = 3.87 \times 10^{-3} \tau_{H_p}^{-1}$ for $q_{\min} \simeq 1.005$ and the stability threshold is at $\delta q_c = 0.012$. Nonlinearly, the profile with $q_{\min} = 1.005$ gives rise to the previously described evolution with the saturation of the velocity norm and the magnetic axis shift requiring about $1000\tau_{H_p}$. The magnetic field lines are plotted for the saturated state in Fig. 27, and they show the pronounced crescent formation and large magnetic axis shift typical of $q \approx 1$ evolutions. For this family of profiles, reasonable time scales for the sawtooth crash and for the magnitude of the shift can be obtained with $\delta q_c - \delta q \approx 3 \times 10^{-3}$.

7. CONCLUSIONS

We have studied the nonlinear evolution of the internal kink in toroidal geometry for shaped cross section plasmas and q profiles such that $q \geq 1$. The results of these studies lead to the following conclusions.

1. Instability grows nonlinearly in the ideal linear time scale, namely several hundred to 1000 poloidal Alfvén times. Magnetic surfaces are not broken by resistive effects on this short time scale.

2. The instability saturates at a finite amplitude, causing a nearly helical shift of the plasma magnetic axis. The plasma displacement deforms the central flux surfaces into a crescent-shaped region and carries outside flux surfaces into the center of the crescent.
3. Shaping effects are relatively weak, but there is strong sensitivity to the q profile and, for low-shear profiles, to β .
4. The nonlinear saturation mechanism is the increase in the field line bending.
5. Evolution times of $10^3 \tau_{H_p}$ and axis shifts of 20% minor radius can be obtained for changes in q profile of only 3×10^{-3} from marginal stability.

These results are consistent with the experimental observations of the fast sawtooth crash process² seen on large tokamaks. The numerically and experimentally determined time scales agree, and the calculated displacement of the magnetic surfaces is highly suggestive of the X-ray tomography measurements on JET. Finally, the sudden transition from stability to robust instability with small changes in q is consistent with the rapid trigger of the experimentally observed fast sawtooth.
